Lecture 12

Travel cost method

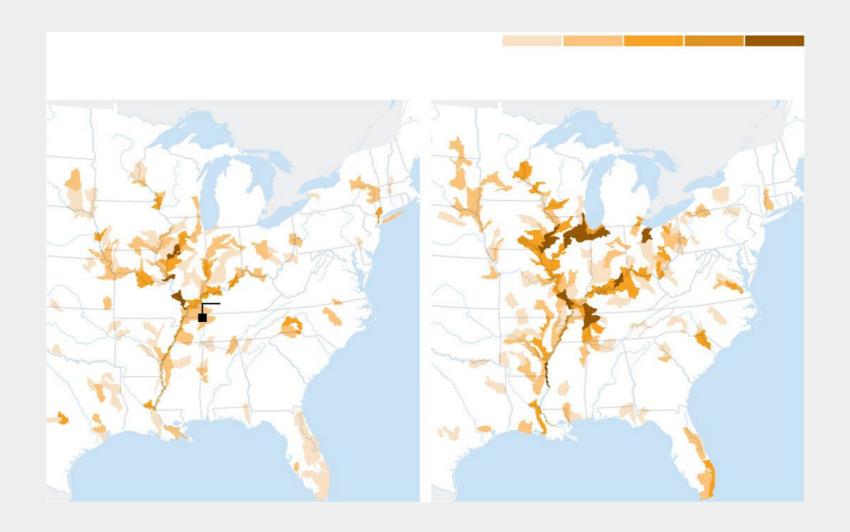

Ivan Rudik AEM 4510

Roadmap

• How do we estimate the value of recreational goods?

Background

The Great Lakes

Carpe diem

Some are worried that Asian carp are poised to invade Lake Michigan

Jul 28th 2012 | From the print edition

WHEN Eric Gittinger, a biologist, goes to work on the Illinois and Mississippi Rivers, he has to look out. The Asian carp that are swimming up from the South, where they escaped from fish farms decades ago, can leap 10 feet in the air or torpedo themselves twice that distance across the water. Larger fish can weigh 40lb (18kg), and Mr Gittinger gets regularly whacked by them.

Yet what most worries people about Asian carp (in fact, several different invasive carp species) is the fact that they are outeating native fish in the rivers, and now seem poised to invade the Great Lakes. This could harm the \$7 billion sport-fishing industry, and damage the ecosystem of the largest body of fresh water in the world.

In 2002 the Army Corps of Engineers
(ACE) installed a series of electric barriers
37 miles downriver in the Chicago Sanitary
and Ship Canal, an artificial channel that
links the lakes with the Mississippi and its
tributaries. But people fear they may not be
working. Recently, multiple traces of Asiancarp DNA have been found in Chicago's
Lake Calumet—far beyond the electric
fence (see map), and a stone's throw from
Lake Michigan.

Benefits from barriers accrue to anglers in the Great Lakes, both commercial and recreational

Costs come from cost of building the barriers plus cost of maintaining them, plus costs of reduced shipping (if any), plus any other costs associated with the barriers

How do we figure out the benefits from recreational anglers?

Recreational areas have value

Recreational areas have value

Their quality also has value

Recreational areas have value

Their quality also has value

Not placing a value on recreation is essentially giving it a value of zero

Recreational areas have value

Their quality also has value

Not placing a value on recreation is essentially giving it a value of zero

This is likely inappropriate

Recreational areas have value

Their quality also has value

Not placing a value on recreation is essentially giving it a value of zero

This is likely inappropriate

If someone dumped toxic waste in Taughannock does that have zero cost?

The travel cost method uses observable data on recreation visitation to infer the recreational value of environmental amenities

The travel cost method uses observable data on recreation visitation to infer the recreational value of environmental amenities

The central idea is that the time and travel cost expenses that people incur to visit a site represent the price of access to the site

The travel cost method uses observable data on recreation visitation to infer the recreational value of environmental amenities

The central idea is that the time and travel cost expenses that people incur to visit a site represent the price of access to the site

This means that people's WTP to visit can be estimated based on the number of visits they make to sites of different prices

The travel cost method uses observable data on recreation visitation to infer the recreational value of environmental amenities

The central idea is that the time and travel cost expenses that people incur to visit a site represent the price of access to the site

This means that people's WTP to visit can be estimated based on the number of visits they make to sites of different prices

This gives us a demand curve for sites/amenities, so we can value changes in these environmental amenities

After WWII, the U.S. national park service solicited advice from economists on methods for quantifying the value of specific park properties

After WWII, the U.S. national park service solicited advice from economists on methods for quantifying the value of specific park properties

Would total entrance fee that people pay measure the value?

After WWII, the U.S. national park service solicited advice from economists on methods for quantifying the value of specific park properties

Would total entrance fee that people pay measure the value?

No!

After WWII, the U.S. national park service solicited advice from economists on methods for quantifying the value of specific park properties

Would total entrance fee that people pay measure the value?

No!

Harold Hotelling proposed the first indirect method for measuring the demand of a non-market good in 1947

Let concentric zones be defined around each park so that the cost of travel to the park from all points in one of these zones is approximately constant. The persons entering the park in a year, or a suitable chosen sample of them, are to be listed according to the zone from which they came. The fact that they come means that the service of the park is at least worth the cost, and this cost can probably be estimated with fair accuracy.

A comparison of the cost of coming from a zone with the number of people who do come from it, together with a count of the population of the zone, enables us to plot one point for each zone on a demand curve for the service of the park. By a judicious process of fitting, it should be possible to get a good enough approximation to this demand curve to provide, through integration, a measure of consumers' surplus..

A comparison of the cost of coming from a zone with the number of people who do come from it, together with a count of the population of the zone, enables us to plot one point for each zone on a demand curve for the service of the park. By a judicious process of fitting, it should be possible to get a good enough approximation to this demand curve to provide, through integration, a measure of consumers' surplus..

About twelve years after, Trice and Wood (1958) and Clawson (1959) independently implemented the methodology

Here's the theory for how we can use observed data to tell us something about willingness to pay

Here's the theory for how we can use observed data to tell us something about willingness to pay

Consider a single consumer and a single recreation site

Here's the theory for how we can use observed data to tell us something about willingness to pay

Consider a single consumer and a single recreation site

The consumer has:

- Total number of recreation trips: x, to site of quality: q
- Total budget of time: T
- Working time: H
- Non-recreation, non-work time: I
- Hourly wage: w
- Money cost of reaching the site: c

This lets us write down the consumer's utility maximization problem:

$$\max_{x,z,l} U(x,z,l,q)$$
 subject to: $\underbrace{wH = cx + z}_{ ext{money budget}}, \; \underbrace{T = H + L + tx}_{ ext{time budget}}$

This lets us write down the consumer's utility maximization problem:

$$\max_{x,z,l} U(x,z,l,q)$$
 subject to: $\underbrace{wH = cx + z}_{ ext{money budget}}, \; \underbrace{T = H + L + tx}_{ ext{time budget}}$

Combine the two constraints to get:

This lets us write down the consumer's utility maximization problem:

$$\max_{x,z,l} U(x,z,l,q)$$
 subject to: $\underbrace{wH = cx + z}_{\text{money budget}}, \underbrace{T = H + L + tx}_{\text{time budget}}$

Combine the two constraints to get:

$$\max_{x,z,l} U(x,z,l,q)$$
 subject to: $\underbrace{wT = z + (c+wt)x + wl}_{\text{combined money/time budget}}$

Let Y=wT be the consumer's *full income*, their money value of total time budget

Let Y=wT be the consumer's *full income*, their money value of total time budget

Let p = c + wt be the consumer's *full price*, their total cost to reach the site

Then we can write the problem as:

Let Y=wT be the consumer's *full income*, their money value of total time budget

Let p = c + wt be the consumer's *full price*, their total cost to reach the site

Then we can write the problem as:

$$\max_{x,z,l} U(x,z,l,q)$$
 subject to: $\underbrace{Y=z+px+wl}_{ ext{combined budget}}$

Let Y=wT be the consumer's *full income*, their money value of total time budget

Let p = c + wt be the consumer's *full price*, their total cost to reach the site

Then we can write the problem as:

$$\max_{x,z,l} U(x,z,l,q)$$
 subject to: $\underbrace{Y=z+px+wl}_{ ext{combined budget}}$

Solve the constraint for z and substitute into the utility function...

$$\max_{x,l} U\left(x,Y-px-wl,l,q
ight)$$

$$\max_{x,l} U\left(x,Y-px-wl,l,q
ight)$$

This has first-order conditions:

$$[x] \,\,\, U_x - p U_z = 0
ightarrow rac{U_x}{U_z} = p$$

and

$$[l] \;\; -wU_z+U_l=0
ightarrow rac{U_l}{U_z}=w$$

 $\frac{U_x}{U_z}=p$ tells us the consumer equates the marginal rate of substitution between recreational trips and consumption to be the full price of the recreational trip

 $\frac{U_x}{U_z}=p$ tells us the consumer equates the marginal rate of substitution between recreational trips and consumption to be the full price of the recreational trip

What does this mean?

 $\frac{U_x}{U_z}=p$ tells us the consumer equates the marginal rate of substitution between recreational trips and consumption to be the full price of the recreational trip

What does this mean?

The value of the recreational trip to the consumer, in dollar terms, is revealed by the full price p

$$U_x - pU_z = 0$$
 $-wU_z + U_l = 0$

The above FOCs are two equations, the consumer had two choices (x,l) so we had two unknowns

We can thus solve for x (and I) as a function of the parameters (p,Y,q):

$$x = f(p, Y, q)$$

This is simply the consumer's **demand curves** for recreation as a function of the full price p, full budget Y, and quality q

$$x = f(p, Y, q)$$

If we observe consumers going to sites of different full prices p_1, p_2, \ldots, p_n , we are moving up and down their recreation demand curve

$$x = f(p, Y, q)$$

If we observe consumers going to sites of different full prices p_1, p_2, \ldots, p_n , we are moving up and down their recreation demand curve

This lets us trace out the demand curve

$$x = f(p, Y, q)$$

If we observe consumers going to sites of different full prices p_1, p_2, \ldots, p_n , we are moving up and down their recreation demand curve

This lets us trace out the demand curve

Changing Y or q shifts the demand curve in or out: these are income and quasi-price effects

$$x = f(p, Y, q)$$

If we observe consumers going to sites of different full prices p_1, p_2, \ldots, p_n , we are moving up and down their recreation demand curve

This lets us trace out the demand curve

Changing Y or q shifts the demand curve in or out: these are income and quasi-price effects

Once we have it, we can compute surplus!

- Construct distance zones (i) as concentric circles emanating from the recreation site
 - Travel costs from all points within each zone to the site are sufficiently close in magnitude to justify neglecting the differences

- Construct distance zones (i) as concentric circles emanating from the recreation site
 - Travel costs from all points within each zone to the site are sufficiently close in magnitude to justify neglecting the differences
- From a sample of visitors (v_i) at the recreation site, determine zones of origin and their populations (n_i)

- Construct distance zones (i) as concentric circles emanating from the recreation site
 - Travel costs from all points within each zone to the site are sufficiently close in magnitude to justify neglecting the differences
- From a sample of visitors (v_i) at the recreation site, determine zones of origin and their populations (n_i)
- Calculate the per capita visitation rates for each zone of origin $(t_i = (v_i/n_i))$

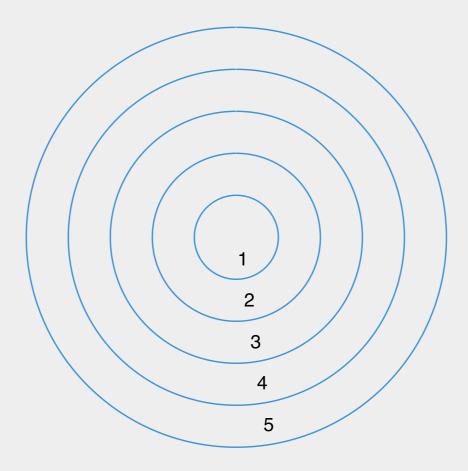

• Construct a travel cost measure (tc_i) that reflects the round-trip costs of travel from the zone of origin to the recreation site (time and gas), + an entry fee (fee) which may be zero and does not vary across zones

- Construct a travel cost measure (tc_i) that reflects the round-trip costs of travel from the zone of origin to the recreation site (time and gas), + an entry fee (fee) which may be zero and does not vary across zones
- Collect relevant socioeconomic data (x_i) such as income and education for each distance zone

- Construct a travel cost measure (tc_i) that reflects the round-trip costs of travel from the zone of origin to the recreation site (time and gas), + an entry fee (fee) which may be zero and does not vary across zones
- Collect relevant socioeconomic data (x_i) such as income and education for each distance zone
- Use statistical methods to estimate the trip demand curve: the relationship between per-capita visitation rates, cost per visit, [and travel costs to other sites (tc_{si})] controlling for socioeconomic differences

- Construct a travel cost measure (tc_i) that reflects the round-trip costs of travel from the zone of origin to the recreation site (time and gas), + an entry fee (fee) which may be zero and does not vary across zones
- Collect relevant socioeconomic data (x_i) such as income and education for each distance zone
- Use statistical methods to estimate the trip demand curve: the relationship between per-capita visitation rates, cost per visit, [and travel costs to other sites (tc_{si})] controlling for socioeconomic differences
- $t_i = g(tc_i + fee; tc_{si}, x_i) + \varepsilon_i$ where g can be linear

Here's a simple example of a set of zones 1-5:

Suppose we have the following data:

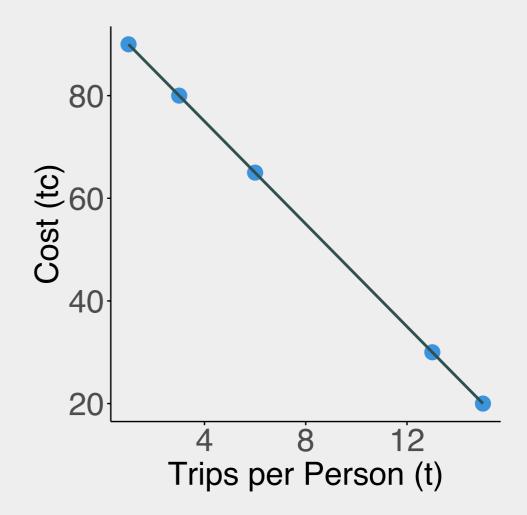

```
## # A tibble: 5 x 5
##
  zone
         dist
              pop cost
                          Vpp
## <chr> <dbl> <dbl> <dbl> <dbl> <
## 1 A
            2 10000
                           15
## 2 B
      30 10000
                   30
                           13
## 3 C
      90 20000
                      65 6
     140 10000
## 4 D
                      80
## 5 E
      150 10000
                      90
```

If we plot cost by visits per person, we have a measure of the demand curve...

This is a very simple example where it happens to be an exactly straight line, most likely the data won't be this perfect

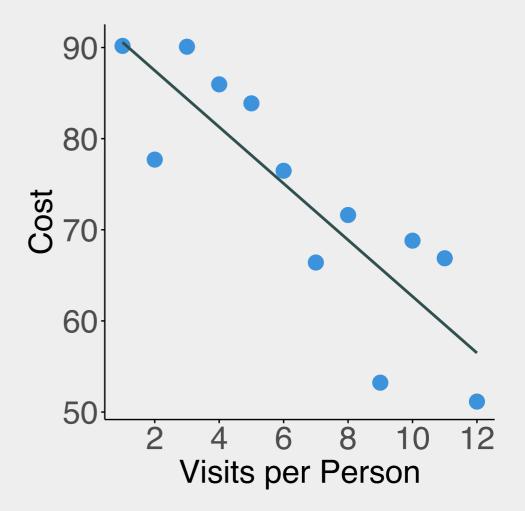

The line is simply from estimating:

$$t_i = \beta_0 + \beta_1 t c_i + \varepsilon_i$$

The data will most likely look like this, but even this is probably too clean

It ignores things like income, other sites, other household characteristics

Based on the estimate model coefficients, construct the (inverse) demand curve

Based on the estimate model coefficients, construct the (inverse) demand curve

For each zone: for each zone, predict total visitation given various fees

Based on the estimate model coefficients, construct the (inverse) demand curve

For each zone: for each zone, predict total visitation given various fees

Entry fee on the y-axis (price), and the number of predicted total visits on the x-axis (quantity)

Based on the estimate model coefficients, construct the (inverse) demand curve

For each zone: for each zone, predict total visitation given various fees

Entry fee on the y-axis (price), and the number of predicted total visits on the x-axis (quantity)

The demand curve is different for different zone because different social economic variables

Based on the estimate model coefficients, construct the (inverse) demand curve

For each zone: for each zone, predict total visitation given various fees

Entry fee on the y-axis (price), and the number of predicted total visits on the x-axis (quantity)

The demand curve is different for different zone because different social economic variables

The (use) value of the park/site to each zone is given by the area underneath the corresponding demand curve

What are some potential issues and concerns with this approach?

What are some potential issues and concerns with this approach?

It ignores non-use value (automatically zero for non-users)

What are some potential issues and concerns with this approach?

It ignores non-use value (automatically zero for non-users)

What are the right zones to choose?

What are some potential issues and concerns with this approach?

It ignores non-use value (automatically zero for non-users)

What are the right zones to choose?

What is the right functional form for demand?

What are some potential issues and concerns with this approach?

It ignores non-use value (automatically zero for non-users)

What are the right zones to choose?

What is the right functional form for demand?

How do we measure the opportunity cost of time?

What are some potential issues and concerns with this approach?

It ignores non-use value (automatically zero for non-users)

What are the right zones to choose?

What is the right functional form for demand?

How do we measure the opportunity cost of time?

How do we treat multi-purpose trips?

What are some potential issues and concerns with this approach?

It ignores non-use value (automatically zero for non-users)

What are the right zones to choose?

What is the right functional form for demand?

How do we measure the opportunity cost of time?

How do we treat multi-purpose trips?

How do we value particular site attributes? Can't disentangle them at a single site

To value particular site attributes we need to have multiple sites (with different attributes!)

To value particular site attributes we need to have multiple sites (with different attributes!)

We can answer questions like:

To value particular site attributes we need to have multiple sites (with different attributes!)

We can answer questions like:

What is the benefit of a fish restocking program?

Need to know the value of fish catch rate for visitors

To value particular site attributes we need to have multiple sites (with different attributes!)

We can answer questions like:

What is the benefit of a fish restocking program?

Need to know the value of fish catch rate for visitors

What is the benefit of water clarity?

To value particular site attributes we need to have multiple sites (with different attributes!)

We can answer questions like:

What is the benefit of a fish restocking program?

Need to know the value of fish catch rate for visitors

What is the benefit of water clarity?

What is the benefit of tree replanting?

Suppose we have a dataset with a large number of individuals and sites

Suppose we have a dataset with a large number of individuals and sites

Individuals are given by $i=1,\ldots,N$ and sites are given by $j=1,\ldots,J$

Suppose we have a dataset with a large number of individuals and sites

Individuals are given by $i=1,\ldots,N$ and sites are given by $j=1,\ldots,J$

We observe the number of times each individual visited each site

Suppose we have a dataset with a large number of individuals and sites

Individuals are given by $i=1,\ldots,N$ and sites are given by $j=1,\ldots,J$

We observe the number of times each individual visited each site

The multi-site model works as follows

Step 1: Do the single-site estimation for each site:

$$T_{ij} = eta_{0j} + eta_{1j} t c_{ij} + eta_{2j} t c_{sij} + eta_{3j} x_i + arepsilon_i j$$

Step 1: Do the single-site estimation for each site:

$$T_{ij} = eta_{0j} + eta_{1j}tc_{ij} + eta_{2j}tc_{sij} + eta_{3j}x_i + arepsilon_i j$$

Step 2: Recover all the β s from each step 1 regression so that we have a set of J β_{0j} s for $j=1\ldots,J,$ β_{1j} s for $j=1\ldots,J,$ etc

These β s tell us the slope (β_{1j}) and intercept $(\beta_{0j}, \beta_{2j}, \beta_{3j})$

 β_{2j} , β_{3j} capture how the cost of substitute sites and household characteristics shift demand up and down

Step 3: Take each set of J coefficients and use them as the dependent variable in a regression on site attributes z:

$$eta_{0j} = lpha_{00} + lpha_{01} z_j + \epsilon_{0j}$$
 $eta_{1j} = lpha_{10} + lpha_{11} z_j + \epsilon_{1j}$
 $eta_{2j} = lpha_{20} + lpha_{21} z_j + \epsilon_{2j}$
 $eta_{3j} = lpha_{30} + lpha_{31} z_j + \epsilon_{3j}$

The $\alpha_{\times 1}$ s tell us how the demand curve shifts $(\alpha_{00}, \alpha_{02}, \alpha_{03})$ or rotates (α_{01}) as we change z

Valuing attributes with a multi-site model

If we improve the quality of a site from z_1 to z_2 , demand for that site shifts up

The gain in CS, holding the cost fixed, is given by the blue area

Once we estimate demand curves, we can see how welfare changes when we alter quality characteristics!
